Effective theory of high-temperature superconductors

Igor F. Herbut
Department of Physics, Simon Fraser University, Burnaby, British Columbia, Canada V5A 1S6

The field theory of a fluctuating d-wave superconductor is constructed and proposed as an effective description of superconducting cuprates at low energies. The theory is used to resolve a puzzle posed by recent experiments on superfluid density in severely underdoped $YBa_2Cu_3O_{6+x}$. In particular, the overall temperature dependence of the superfluid density at low dopings is argued to be described well by the strongly anisotropic weakly interacting Bose gas, and thus approximately linear in temperature with an almost doping-independent slope.

The superconducting state of underdoped high-temperature superconductors is long known to be anomalous. Whereas the pseudogap temperature T^* is high, and only increasing with underdoping, the superconducting transition temperature T_c, together with the zero-temperature superfluid density $\rho(0)$ at the same time is continuously vanishing [1]. This is in stark contrast to the predictions of the standard BCS theory, in which of course T_c and T^* would be essentially identical, and $\rho(0)$ proportional to the electron density, i. e. $\rho(0) \sim 1-x$, where x is the number of holes per lattice site (doping). It has recently been argued [2], [3], that when pairing in the d-wave channel is accompanied by strong repulsion the amplitude of the order parameter $|\Delta|$ and $\rho(0)$ may behave oppositely as half-filling ($x=0$) is approached, with the divorce of T^* and T_c arising as a natural consequence. Disordering of the d-wave superconductor (dSC) by quantum fluctuations thus appears, at least in this respect, to be similar to doping of holes into the Mott insulator (MI) as described by the effective gauge theories of the t-J model [4].

There exist, however, experimental results that appear to contradict the theories of the fluctuating dSC [5], [6], [7], or the gauge theories of the t-J model [4]. Whereas these approaches correctly yield $\rho(0) \sim x$ as has been seen, they also generally imply that the 'effective charge' of quasiparticles becomes proportional to doping [8], and thus $d\rho(T)/dT|_{T\rightarrow 0} \sim x^2$, which has not. On the contrary, the experiments in strongly underdoped single crystals [9] and thin films [10] of $YBa_2Cu_3O_{6+x}$ (YBCO) show the superfluid density to be approximately linear in temperature over most of the temperature range, with an almost doping-independent slope, and with a higher power-law emerging near $T=0$. The critical region, almost 10 Kelvins wide at optimal doping, appears also to have completely disappeared at low dopings. The doping-independent slope becomes particularly troubling in light of the recent measurements of heat transport in high-purity single crystals of YBCO [11], in which gapless quasiparticles in strongly underdoped samples indeed appear decoupled from the external magnetic field. This would agree with the theoretical prediction that quasiparticles should gradually become 'neutral' with underdoping, but at the same time makes the behavior of the superfluid density all the more puzzling.

In this Letter I present the field theory of the quantum-fluctuating d-wave superconductor (dSC). The spin sector, which was the primary focus of the earlier studies [6], [7], [12], has been embedded into a more general framework describing both spin and charge degrees of freedom at finite dopings. The theory describes nodal quasiparticles coupled to the phase fluctuations of the order parameter. Quantum fluctuations should arise from the Coulomb interaction, which becomes increasingly detrimental to phase coherence near half-filling [3]. Such an effective theory should provide a correct description at energies below the amplitude $|\Delta|$. From this starting point two main results are further derived. First, the general theory is shown to be considerably simplified by being rewritten in terms of the dual variables. Remarkably, in this form it resembles the effective SU(2) gauge theory of the t-J model [4]. Second, the transformed theory facilitates a simple, and a physically transparent calculation of the ab-plane superfluid density $\rho(T)$ in the relevant doping regime. Although the quasiparticle 'charge' is found to indeed be gradually vanishing, on the scale of T_c the region of temperatures where the slope of $\rho(T)$ would become too strongly doping-dependent becomes negligible at low dopings. In the leading approximation, the overall form of $\rho(T)$ is given by the condensate of the strongly anisotropic weakly-interacting three-dimensional Bose gas. This, on the other hand, is shown to be $\Delta\rho(T) \sim T\ln(T/t)$, with t as the Josephson interlayer coupling, and thus also approximately linear in temperature, but with the slope at most logarithmically dependent on doping. This also explains the absence of a discernible critical region and a slight curvature of the data near $T=0$ (Fig. 1). Finally, properties of the insulating phase at $x=0$ are briefly discussed.

Let me begin by postulating the action for the low-energy quasiparticles of a two-dimensional (2D) phase-fluctuating dSC, $S = \int_0^{1/T} d\tau \int d^2\vec{x} L$, with the Lagrangian density $L = L_\Psi + L_\Phi$, and

$$L_\Psi = \bar{\Psi}_1[\gamma_0(\partial_\tau - ia_0) + v_F\gamma_1(\partial_x - ia_x) + v_\Delta\gamma_2(\partial_y - ia_y)]\Psi_1 + (1\rightarrow 2, x\leftrightarrow y) + iJ_\mu(v_\mu + A_\mu), \tag{1}$$

$$L_\Phi = \frac{i}{\pi}\epsilon_{\mu\nu\rho}(a_\mu, v_\mu)\partial_\nu(A_\rho^-, A_\rho^+)^T + \frac{K_\mu}{2}(v_\mu + A_\mu)^2 + \frac{h}{\pi}\epsilon_{0\mu\nu}\partial_\mu A_\nu^+ + \frac{1}{2}\sum_{n=1}^{2}|(\partial_\mu - i(A_\mu^+ + (-)^n A_\mu^-))\Phi_n|^2 \tag{2}$$

$$+\tilde{\alpha}\sum_{n=1}^{2}|\Phi_n|^2+\frac{\tilde{\beta}_1}{2}(\sum_{n=1}^{2}|\Phi_n|^2)^2+\frac{\tilde{\beta}_2}{2}\sum_{n=1}^{2}|\Phi_n|^4.$$

Two four-component fermionic fields $\Psi_{1,2}$ describe the gapless spin-1/2 excitations near the two pairs of diagonally opposed nodes. v_F and $v_\Delta \sim |\Delta|$ are the two characteristic velocities of the low-energy spectrum, $\{\gamma_\mu, \gamma_\nu\} = 2\delta_{\mu\nu}$, and J_μ and $\bar{\Psi}_n\gamma_\mu\Psi_n$, $\mu = 0, 1, 2$ are the charge and spin currents, respectively, as defined in [7]. Whereas the Fermi velocity v_F should be approximately independent of x, v_Δ may be assumed to be a decreasing function of doping [2], [3]. a_μ and v_μ are the Berry and the Doppler $U(1)$ fields that furnish the coupling of the quasiparticles to the fluctuating phase of the order parameter [6]; the integration over the auxiliary gauge fields $A^{\pm}_\mu$ constrains $\epsilon_{\mu\nu\rho}\partial_\nu(a_\rho, v_\rho) = \pi(J_{\Phi_1} - J_{\Phi_2}, J_{\Phi_1} + J_{\Phi_2})_\mu$, where $J_{\Phi_{1,2}}$ are the vortex current densities. K_0 and $K_{1,2} = K \sim E_F \sim 1 - x$ are the bare compressibility and the bare superfluid density, respectively, which derive from the integration over the high-energy fermions. A_μ is the physical electromagnetic vector potential, and h the bare chemical potential. The parameter $\tilde{\alpha}$ tunes quantum fluctuations, and $\tilde{\beta}_{1,2} > 0$ describe the short-range repulsive interactions between vortex loops. Terms that are irrelevant at low-energies [13] have been omitted.

At $h = 0$ L_Φ represents the continuum limit of the lattice theory discussed in [7]. Its form may be also understood on the basis of symmetry: 1) the usual electromagnetic gauge invariance under $A_\mu \rightarrow A_\mu + \partial_\mu\chi$, 2) the internal gauge invariance under $a_\mu \rightarrow a_\mu + \partial_\mu\chi$, 3) the Ising symmetry under $\Phi_1 \leftrightarrow \Phi_2$, $a_\mu \leftrightarrow -a_\mu$, spin up↔down, and 4) the gauge invariance under $A^{\pm}_\mu \rightarrow A^{\pm}_\mu + \partial_\mu\chi^{\pm}$, together with the requirement of analyticity in $\Phi_{1,2}$ dictate the form of L as unique to the lowest non-trivial order in the fields and their derivatives. An important feature of the Lagrangian is the addition of the chemical potential h, which is necessary to allow for a finite doping. It is introduced by shifting $A_0 \rightarrow A_0 + ih$, after which it has been absorbed into a redefined v_0, as $v_0 + ih \rightarrow v_0$. It then appears only as the fictitious external 'magnetic field' in the τ-direction in L_Φ. As will be discussed shortly, having $h \neq 0$ is crucial for obtaining the correct charge dynamics of the fluctuating dSC.

The form of L may also be justified on phenomenological grounds, since, as discussed below, it describes a novel MI-dSC transition of possible relevance to cuprates. It is convenient, however, to derive the equivalent *dual* form of L_Φ, more amenable at $h \neq 0$, first. Duality is most precisely established on a lattice, and for the 'hard-spin' version of the complex fields. Using a fairly standard set of transformations [14] it is easy to show that, modulo analytic terms,

$$\int(\prod_r d\phi_r d\vec{A}_r)e^{\sum_r \frac{1}{T}\cos(\Delta\phi-2\vec{A})-\frac{i}{\pi}\vec{a}\cdot\Delta\times\vec{A}} = \tag{3}$$

$$\lim_{t\rightarrow 0}\int(\prod_r d\psi_r)e^{\sum_r \frac{1}{t}\cos(\Delta\psi-\vec{a})-\frac{T}{8\pi^2}(\Delta\times\vec{a})^2},$$

where r labels the sites of the 2+1D quadratic lattice, and Δ and $\Delta\times$ are the lattice gradient and the curl. Taking the continuum limit and going into the 'soft-spin' representation [14] this implies that

$$L_\Phi = \frac{K_\mu}{2}(v_\mu + A_\mu)^2 + h\sum_{n=1}^{2} b^*_n(\partial_0 - i(v_0 + (-)^n a_0))b_n \tag{4}$$

$$+\frac{1}{2}\sum_{n=1}^{2}|(\partial_\mu - i(v_\mu + (-)^n a_\mu))b_n|^2$$

$$+(\alpha - \frac{h^2}{2})\sum_{n=1}^{2}|b_n|^2 + \frac{\beta_1}{2}(\sum_{n=1}^{2}|b_n|^2)^2 + \frac{\beta_2}{2}\sum_{n=1}^{2}|b_n|^4.$$

L_Φ may therefore be alternatively understood as describing the coupling of the fields a_μ and v_μ to *two non-relativistic* bosonic fields of unit electromagnetic charge, which are dual to the original vortex fields $\Phi_{1,2}$. It is interesting to note that, although presumably more general, Eq. 4 is similar to the conjectured effective theory of the s-flux phase within the $SU(2)$ gauge theory of the t-J model [4]. Somewhat similar connection between the U(1) gauge theory of the t-J model and the dSC with topologically trivial phase fluctuations [5] has been noted in the past [15], [16].

Consider the *superconducting phase* described by L. Assuming $\alpha > 0$, $\beta_{1,2} > 0$ and minimizing L_Φ, for $h > \sqrt{2\alpha}$ one finds $|\langle b_1\rangle|^2 = |\langle b_2\rangle|^2 = (h^2 - h_c^2)/2(2\beta_1 + \beta_2)$. To the quadratic order L_Φ then reduces as

$$L_\Phi \rightarrow \frac{K_\mu}{2}(v_\mu + A_\mu)^2 + \frac{\rho_b(T)}{2}(v^2_\mu + a^2_\mu) - ihn_b v_0, \tag{5}$$

where $\rho_b(T)$ and n_b are the superfluid and the total density of the bosons, respectively. Since both $U(1)$ fields are massive, nodal quasiparticles interact only via short-range interactions, and therefore represent well-defined low-energy excitations, conducting heat, for example. At low energies $L = L_{sp} + L_{ch}$, where the spin part of the Lagrangian to the leading order is $L_{sp} = L_\Psi - iJ_\mu(v_\mu + A_\mu) + (\rho_b/2)a^2_\mu$ [12], and

$$L_{ch} = iJ_\mu(v+A)_\mu + \frac{K_\mu}{2}(v+A)^2_\mu + \frac{\rho_b(T)}{2}v^2_\mu - ihn_b v_0. \tag{6}$$

Setting $A_0 = 0$ and integrating over v_0 one finds

$$L_{ch} = \frac{J_0^2}{2(K_0 + \rho_b(T))} - \frac{hn_b}{K_0 + \rho_b(T)}J_0 + \tag{7}$$

$$i\vec{J}\cdot(\vec{v} + \vec{A}) + \frac{K}{2}(\vec{v} + \vec{A})^2 + \frac{\rho_b(T)}{2}\vec{v}^2,$$

where $\vec{X} = (X_1, X_2)$. The first term describes a short-range repulsion between fermions and as such is irrelevant at low energies. The second determines the renormalized chemical potential: $\mu(T) = -hn_b/(K_0 + \rho_b(T))$. Since $x \sim -\mu(0)$, one finds $n_b \sim x$. The rest of L_{ch} determines the superfluid density. Integrating $\vec{v}$ generates the term $z\vec{J}\cdot\vec{A}$ in L_{ch}, with the ratio $z = \rho_b(T)/(K + \rho_b(T))$ as

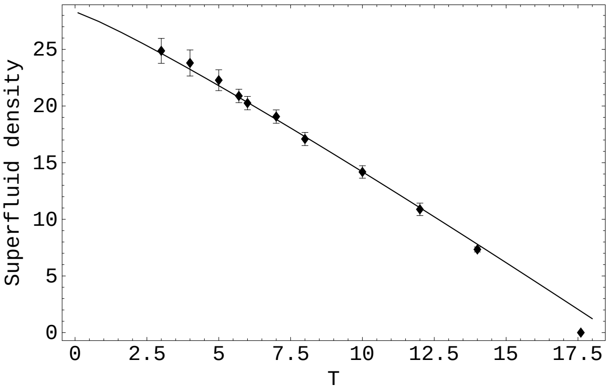

FIG. 1: H_{c1} in an underdoped YBCO [9] converted to ab-plane superfluid density in Kelvins [17] as $\rho = (4\pi H_{c1}/((\ln(\kappa)+0.5)20.7Gauss))(6.2K)(c/10\text{Å})$, for $\kappa = 100$ and the c-axis anisotropy 10^{-4} [20]. The line is $\rho_b(T)$ from the Eq. 9. with $\rho_b(0) = 28.3K$.

the Fermi liquid 'charge renormalization' parameter. The electromagnetic field gradually decouples from quasiparticles with underdoping, in accord with the observed insensitivity of thermal conductivity to the magnetic field in underdoped YBCO [11].

The suppression of the quasiparticle charge, and particularly its effect on the superfluid density, may be alternatively understood by integrating fermions in L *before* $\vec{v}$. At $T \neq 0$, this reduces K in Eq. 7 as: $K \to K(T) = K - (2\ln(2)/\pi)(v_F/v_\Delta)T + O(T^2)$. Integrating then $\vec{v}$ yields the total superfluid density:

$$\rho(T)^{-1} = K(T)^{-1} + \rho_b(T)^{-1}. \tag{8}$$

The last result, also known as Ioffe-Larkin rule [4], is easily seen to hold both in the underdoped (large K), and in the overdoped regime (large $\rho_b(0)$). At $T = 0$, therefore, $\rho(0) = K\rho_b(0)/(K + \rho_b(0)) \sim n_b \sim x$ at low x, which agrees qualitatively with more microscopic calculations [2], [3], as well as with experiment [1]. At $T \neq 0$, however, $\rho_b(0) - \rho_b(T) \propto T^3$ in 2D [17], and the leading temperature dependence of $\rho(T)$ at low T comes from the first, quasiparticle, term in Eq. 8. Differentiation gives $d\rho(T)/dT = (\rho(0)/K)^2 dK(T)/dT \sim z^2$ at low T. Such a strong, $\sim \rho^2(0)$, dependence of the slope with doping, however, appears to be clearly contradicting the experiment [9], which defines our main problem.

While the reasoning from the previous paragraph is correct in principle, the range of temperatures where it applies clearly depends on the specific form of the bosonic term in Eq. 8. One needs therefore to understand $\rho_b(T)$ in the underdoped region, which corresponds to the *dilute* system of bosons, in more detail. Before turning to the case of cuprates, let me first briefly review a canonical example of bosons with a mass m interacting with a two-body interaction $V(\vec{x}) = \lambda\delta(\vec{x})$. Dimensional analysis dictates that the superfluid density in an isotropic 3D system may be written as $\rho_b = r^{-3}G(m\lambda/r, mTr^2)$, where r is the average distance between particles, and $G(x, y)$ a dimensionless function of two dimensionless arguments, with $G(0, 0) = 1$. The dilute limit $r \to \infty$ is equivalent therefore to the weakly interacting high-temperature limit, where $G \approx 1 - (T/T_{BEC})^{3/2}$. This is just the temperature dependence of the *condensate of non-interacting bosons*, with T_{BEC} being the Bose-Einstein condensation temperature. At low temperatures, of course, interactions always turn the temperature behavior into $\sim T^4$ (in 3D), but this higher power-law sets in only below the characteristic interaction temperature scale $\Delta T_\lambda \sim (m\lambda/r)T_{BEC}$. Similarly, the critical region $\Delta T_c \sim (m\lambda/r)^2 T_{BEC}$, so both $\Delta T_{\lambda,c} \ll T_c \approx T_{BEC}$ in the dilute regime. This is all just another way of phrasing the *irrelevancy* of short-range interactions near the quantum critical point of 3D bosons. Short-range interactions are irrelevant in 2D as well but only marginally so, and consequently the weakly interacting regime is harder to reach. Nevertheless, in either case the bosonic superfluid density in the sufficiently dilute regime approaches the characteristic temperature dependence of the condensate, $\Delta\rho_b(T) \sim T^{D/2}$, except in the narrow low-temperature and critical regions [18].

What is the function $\rho_b(T)$ then in severely underdoped cuprates? First, the phase coherence in the superconducting state is known to be strongly anisotropic, but nevertheless fully three-dimensional. We may include this feature by additionally coupling the different superconducting layers, each described by Eq. 4 and labeled by l, via a weak Josephson coupling of the form $t\sum_{l,n=1,2} b^*_{n,l} b_{n,l+1}$, with $t \ll \rho_b(0)$. Second, in such a strongly anisotropic system the Coulomb interaction within a layer is screened well by the other layers, and except at extremely low densities $\rho_b(0) \sim t$ it may indeed be taken to be effectively short-ranged [19], as in Eq. 4. Away from the ultimate quantum critical region of the theory (1) where both the long-range nature of the Coulomb repulsion, and possibly the gauge field fluctuations, would finally become important, such a short-range interaction is then irrelevant, and $\rho_b(T)$ to the zeroth order in interaction is just the condensate of the non-interacting system. In the anisotropic 3D case this gives $\rho_b(T) = \rho_b(0) - TF(t/T)/(2\pi)$, where

$$F(x) = -\int_0^1 dz \ln(1 - e^{-x\sin^2(\pi z/2)}), \tag{9}$$

with $F \approx 2.612(T/\pi t)^{1/2}$ for $T \ll t$, and $F \approx \ln(T/t)$ for $t \ll T$. Since $t \ll \rho_b(0)$, on the scale of T_c $\rho_b(T)$ behaves approximately linearly with temperature. This being the case, it is now the bosonic term in Eq. 4 that determines the form of $\rho(T)$ everywhere, except at temperatures below $\sim tx^4$. Furthermore, assuming the $T = 0$ c-axis superfluid response to be also determined by the bosonic component fixes the parameter t: at low dopings $t = 2ab\rho_c(0)/(xc^2)$, where $x/(abc)$ is the boson density, a, b and c are the dimensions of the unit cell in the a-, b-, and c-directions, and $\rho_c(0)$ the c-axis superfluid density (in Kelvins [17]). As an illustration, taking $x \approx ab/c^2 \approx 0.1$ and the measured value [20] of $\rho_c(0)/\rho(0) = 10^{-4}$, a satisfactory fit to experimental data [9] is achieved even by neglecting the quasiparticle term in Eq. 8 completely, and by adjusting only $\rho_b(0)$ (Fig. 1). In the overdoped regime, on the other hand, $\rho_b(T) \gg K(T)$, and $\rho(T)$ should cross to the standard BCS result, as may have been already observed [21].

For completeness, I also briefly describe the *non-superconducting phase* of L. For $h < \sqrt{2\alpha}$, $\langle b_1 \rangle = \langle b_2 \rangle = 0$, and the bosons are in the incompressible phase. The integration over the bosons then yields

$$L_\Phi \to \frac{K_\mu}{2}(v_\mu + A_\mu)^2 + \frac{(\epsilon_{\mu\nu\rho}\partial_\nu v_\rho)^2}{2m_b} + \frac{(\epsilon_{\mu\nu\rho}\partial_\nu a_\rho)^2}{2m_b}, \quad (10)$$

to quadratic order, where $m_b^2 \sim \alpha + O(\beta_{1,2})$. At low energies one may still write $L = L_{sp} + L_{ch}$, but now with L_{sp} as the three dimensional quantum electrodynamics (QED_3) [6], [7]. Quasiparticles interact via long-range gauge interaction and cease to be sharp excitations. Furthermore, fermions may acquire a very small mass, $\leq 10^{-4} m_b$ [22], which would imply the antiferromagnetic ordering in the system. L_{ch}, on the other hand, after the integration over v_μ becomes

$$L_{ch} \to \frac{(\epsilon_{\mu\nu\rho}\partial_\nu A_\rho)^2}{2m_b} + \frac{i\epsilon_{\mu\nu\rho}\partial_\nu J_\rho \epsilon_{\mu\alpha\beta}\partial_\alpha A_\beta}{K_\mu m_b} + \frac{J_\mu^2}{2K_\mu}. \quad (11)$$

The first term implies that the system is an *insulator* with a charge gap $\sim m_b$. The second term after a partial integration may be rewritten as $\sim J_\mu \epsilon_{\mu\nu\rho}\partial_\nu B_\rho$, where $B_\rho = \epsilon_{\rho\mu\nu}\partial_\mu A_\nu$, so a uniform magnetic field becomes completely decoupled in the insulator. Since the lifetime of fermions is inversely proportional to the fermion mass, and thus likely to be very long, thermal conductivity in the insulator should essentially remain the same. This could explain why the thermal conductivity of even a weakly insulating YBCO apparently remains linear in temperature [11].

It may be noteworthy that L also has a *metastable* state for $h > h_c$, with $\langle b_1 \rangle = 0$, and $2|\langle b_2 \rangle|^2 = (h^2 - h_c^2)/(\beta_1 + \beta_2)$. In this state $L_\Phi \to \rho_b(v_\mu + a_\mu)^2/2 - ihn_b(v_0 + a_0)$, to quadratic order. Although $\rho_b \neq 0$, the full system is then actually metallic, since fermions acquire back their full electromagnetic charge and form four hole pockets with a small Fermi surface, $\sim h$.

To summarize, the proposed effective theory predicts that a weakly fluctuating d-wave BCS superconductor at large dopings crosses over to the strongly phase-fluctuating regime in the pseudogap, low-doping regime, and ultimately suffers a transition into the insulator with possible antiferromagnetic order. Superfluid density as a function of temperature at low dopings becomes well approximated by the Bose condensate in the strongly anisotropic 3D Bose gas, and thus appears linear with an essentially doping-independent slope over most of the temperature range.
